

1 The Naive Bayes classification method

1.1 Introduction

In our discussion of Bayes Theorem, we looked at a situation in which we had a population consisting of people infected with COVID-19 and people not infected, and we had a test that we could apply to determine which class an individual belonged to. Because our test was not 100 percent reliable, a positive test result didn't guarantee that a person was infected, and we used Bayes Theorem to evaluate how to interpret the positive test result. More specifically, our information about the test performance gave us the conditional probabilities of positive and negative test results given infection status – so for example we were given $P(+|\text{infected})$, the chance of getting a positive test assuming the person is infected – and we used Bayes Theorem to determine $P(\text{infected}|+)$, the chance that a person was infected given a positive test result.

The Naive Bayes classification method is a generalization of this idea. We have data that belongs to one of two classes, and based on the results of a series of tests, we wish to decide which class a particular data point belongs to. For one example, we are given a collection of product reviews from a website and we wish to classify those reviews as either “positive” or “negative.” This type of problem is called “sentiment analysis.” For another, related example, we have a collection of emails or text messages and we wish to label those that are likely “spam” emails. In both of these examples, the “test” that we will apply is to look for the appearance or absence of certain key words that make the text more or less likely to belong to a certain class. For example, we might find that a movie review that contains the word “great” is more likely to be positive than negative, while a review that contains the word “boring” is more likely to be negative.

The reason for the word “naive” in the name of this method is that we will derive our probabilities from empirical data, rather than from any deeper theory. For example, to find the probability that a negative movie review contains the word “boring,” we will look at a bunch of reviews that our experts have said are negative, and compute the proportion of those that contain the word boring. Indeed, to develop our family of tests, we will rely on a training set of already classified data from which we can determine estimates of probabilities that we need.

1.2 An example dataset

To illustrate the Naive Bayes algorithm, we will work with the “Sentiment Labelled Sentences Data Set” ([1]). This dataset contains 3 files, each containing 1000 documents labelled 0 or 1 for “negative” or “positive” sentiment. There are 500 of each type of document in each file. One file contains reviews of products from amazon.com; one contains yelp restaurant reviews, and one contains movie reviews from imdb.com.

Let's focus on the amazon reviews data. Here are some samples:

```

So there is no way for me to plug it in here in the US unless I go by a
converter. 0
Good case, Excellent value. 1
Great for the jawbone. 1
Tied to charger for conversations lasting more than 45 minutes.MAJOR
PROBLEMS!! 0
The mic is great. 1
I have to jiggle the plug to get it to line up right to get decent volume
. 0
If you have several dozen or several hundred contacts, then imagine the
fun of sending each of them one by one. 0
If you are Razr owner...you must have this! 1
Needless to say, I wasted my money. 0
What a waste of money and time!. 0

```

As you can see, each line consists of a product review followed by a 0 or 1; in this file the review is separated from the text by a tab character.

1.3 Bernoulli tests

We will describe the “Bernoulli” version of a Naive Bayes classifier for this data. The building block of this method is a test based on a single word. For example, let’s consider the word **great** among all of our amazon reviews. It turns out that **great** occurs 5 times in negative reviews and 92 times in positive reviews among our 1000 examples. So it seems that seeing the word **great** in a review makes it more likely to be positive. The appearances of great are summarized in table 1 . We write $\sim\text{great}$ for the case where **great** does *not* appear.

Table 1: Occurrences of **great** by type of review .

	+	-	total
great	92	5	97
$\sim\text{great}$	408	495	903
total	500	500	1000

In this data, positive and negative reviews are equally likely so $P(+) = P(-) = .5$. From this table, and Bayes Theorem, we obtain the empirical probabilities (or “naive” probabilities).

$$P(\text{great}|+) = \frac{92}{500} = .184$$

and

$$P(\text{great}) = \frac{97}{1000} = .097$$

Therefore

$$P(+|\mathbf{great}) = \frac{.184}{.097}(.5) = 0.948.$$

In other words, *if* you see the word **great** in a review, there’s a 95% chance that the review is positive.

What if you *do not* see the word **great**? A similar calculation from the table yields

$$P(+|\sim \mathbf{great}) = \frac{408}{903} = .452$$

In other words, *not* seeing the word **great** gives a little evidence that the review is negative (there’s a 55% chance it’s negative) but it’s not that conclusive.

The word **waste** is associated with negative reviews. It’s statistics are summarized in table 2.

Table 2: Occurrences of **waste** by type of review .

	+	-	total
waste	0	14	14
~waste	500	486	986
total	500	500	1000

Based on this data, the “naive” probabilities we are interested in are:

$$P(+|\mathbf{waste}) = 0$$

$$P(+|\sim \mathbf{waste}) = .51$$

In other words, if you see **waste** you definitely have a negative review, but if you don’t, you’re only slightly more likely to have a positive one.

What about combining these two tests? Or using even more words? We could analyze our data to count cases in which both **great** and **waste** occur, in which only one occurs, or in which neither occurs, within the two different categories of reviews, and then use those counts to estimate empirical probabilities of the joint events. But while this might be feasible with two words, if we want to use many words, the number of combinations quickly becomes huge. So instead, we make a basic, and probably false, assumption, but one that makes a simple analysis possible.

Assumption: We assume that the presence or absence of the words **great** and **waste** in a particular review (positive or negative) are independent events.

More generally, given a collection of words w_1, \dots, w_k , we assume that their occurrences in a given review are independent events.

Independence means that we have

$$\begin{aligned} P(\mathbf{great}, \mathbf{waste}|\pm) &= P(\mathbf{great}|\pm)P(\mathbf{waste}|\pm) \\ P(\mathbf{great}, \sim \mathbf{waste}|\pm) &= P(\mathbf{great}|\pm)P(\sim \mathbf{waste}|\pm) \\ &\vdots \end{aligned}$$

So for example, if a document contains the word **great** and does *not* contain the word **waste**, then the probability of it being a positive review is:

$$P(+|\mathbf{great}, \sim \mathbf{waste}) = \frac{P(\mathbf{great}|+)P(\sim \mathbf{waste}|+)P(+)}{P(\mathbf{great}, \sim \mathbf{waste})}$$

while the probability of it being a negative review is

$$P(-|\mathbf{great}, \sim \mathbf{waste}) = \frac{P(\mathbf{great}|-)P(\sim \mathbf{waste}|-)P(-)}{P(\mathbf{great}, \sim \mathbf{waste})}$$

Rather than compute these probabilities (which involves working out the denominators), let's just compare them. Since they have the same denominators, we just need to compare numerators, which we call L for likelihood: Using the data from table 1 and table 2, we obtain:

$$L(+|\mathbf{great}, \sim \mathbf{waste}) = (.184)(1)(.5) = .092$$

and

$$L(-|\mathbf{great}, \sim \mathbf{waste}) = (.01)(.028)(.5) = .00014$$

so our data suggests strongly that this is a positive review.

1.4 Feature vectors

To generalize this, suppose that we have extracted keywords w_1, \dots, w_k from our data and we have computed the empirical values $P(w_i|+)$ and $P(w_i|-)$ by counting the fraction of positive and negative reviews that contain the word w_i :

$$P(w_i|\pm) = \frac{\text{number of } \pm \text{ reviews that mention } w_i}{\text{number of } \pm \text{ reviews total}}$$

Notice that we only count *reviews*, not *occurrences*, so that if a word occurs multiple times in a review it only contributes 1 to the count. That's why this is called the *Bernoulli* Naive Bayes – we are thinking of each keyword as yielding a yes/no test on each review.

Given a review, we look to see whether each of our k keywords appears or does not. We encode this information as a vector of length k containing 0's and 1's indicating the absence or presence of the k th keyword. Let's call this vector the *feature vector* for the review.

For example, if our keywords are $w_1 = \mathbf{waste}$, $w_2 = \mathbf{great}$, and $w_3 = \mathbf{useless}$, and our review says

This phone is useless, useless, useless! What a waste!

then the associated feature vector is $f = (1, 0, 1)$.

For the purposes of classification of our reviews, we are going to forget entirely about the text of our reviews and work only with the feature vectors. From an abstract perspective, then, by choosing our k keywords, our “training set” of N labelled reviews can be replaced by an $N \times k$ matrix $X = (x_{ij})$ with entries 0 or 1, where $x_{ij} = 1$ if and only if the j^{th} keyword appears in the i^{th} review.

The labels of 0 or 1 for unfavorable or favorable reviews can also be packaged up into a $N \times 1$ vector Y that serves as our “target” variable.

Setting things up this way lets us express the computations of our probabilities $P(w_i|\pm)$ in vector form. In fact, $Y^\top X$ is the sum of the rows of X corresponding to positive reviews, and therefore, letting N_\pm denote the number of \pm reviews,

$$P_+ = \frac{1}{N_+} Y^\top X = \begin{bmatrix} P(w_1|+) & P(w_2|+) & \cdots & P(w_k|+) \end{bmatrix}.$$

Similarly, since Y and X have zero and one entries only, if we write $1 - Y$ and $1 - X$ for the matrices obtained by replacing every entry z by $1 - z$ in each matrix, we have:

$$P_- = \frac{1}{N_-} (1 - Y)^\top X = \begin{bmatrix} P(w_1|-) & P(w_2|-) & \cdots & P(w_k|-) \end{bmatrix}.$$

Note that the number of positive reviews is $N_+ = Y^\top Y$ and the number of negative ones is $N_- = N - N_+$. Since $P(+)$ is the fraction of positive reviews among all reviews, we can compute it as $P(+) = \frac{1}{N} Y^\top Y$, and $P(-) = 1 - P(+)$.

1.5 Likelihood

If a review has an associated feature vector $f = (f_1, \dots, f_k)$, then by independence the probability of that feature vector occurring within one of the \pm classes is

$$P(f|\pm) = \prod_{i:f_i=1} P(w_i|\pm) \prod_{i:f_i=0} (1 - P(w_i|\pm))$$

which we can also write

$$P(f|\pm) = \prod_{i=1}^k P(w_i|\pm)^{f_i} (1 - P(w_i|\pm))^{(1-f_i)}. \quad (1)$$

These products aren't practical to work with – they are often the product of many, many small numbers and are therefore really tiny. Therefore it's much more practical to work with their logarithms.

$$\log P(f|\pm) = \sum_{i=1}^k f_i \log P(w_i|\pm) + (1 - f_i) \log(1 - P(w_i|\pm)) \quad (2)$$

If we have a group of reviews N organized in a matrix X , where each row is the feature vector associated to the corresponding review, then we can compute all of this at once. We'll write $\log P_{\pm} = \log P(X|\pm)$ as the row vector whose i^{th} entry is $\log P(f_i|\pm)$:

$$\log P(X|\pm) = X(\log P_{\pm})^{\top} + (1 - X)(\log(1 - P_{\pm}))^{\top}. \quad (3)$$

By Bayes Theorem, we can express the chance that our review with feature vector f is positive or negative by the formula:

$$\log P(\pm|f) = \log P(f|\pm) + \log P(\pm) - \log P(f)$$

where

$$P(\pm) = \frac{\text{the number of } \pm \text{ reviews}}{\text{total number of reviews}}$$

and $P(f)$ is the fraction of reviews with the given feature vector. (Note: in practice, some of these probabilities will be zero, and so the log will not be defined. A common practical approach to dealing with this is to introduce a “fake document” into both classes in which every vocabulary word appears – this guarantees that the frequency matrix will have no zeros in it).

A natural classification rule would be to say that a review is positive if $\log P(+|f) > \log P(-|f)$, and negative otherwise. In applying this, we can avoid computing $P(f)$ by just comparing $\log P(f|+) + \log P(+)$ and $\log P(f|-) + \log P(-)$ computed using eq. 2. Then we say:

- a review is positive if $\log P(f|+) + \log P(+)$ > $\log P(f|-) + \log P(-)$ and negative otherwise.

Again we can exploit the matrix structure to do this for a bunch of reviews at once. Using eq. 3 and the vectors P_{\pm} we can compute column vectors corresponding to both sides of our decision inequality and subtract them. The positive entries indicate positive reviews, and the negative ones, negative reviews.

1.6 Other applications

We developed the Naive Bayes method for sentiment analysis, but once we chose a set of keywords our training data was reduced to an $N \times k$ matrix X of 0/1 entries, together with an $N \times 1$ target column vector Y . Then our classification problem is to decide whether a given vector of k entries, all 0 or 1, is more likely

to carry a 0 or 1 label. All of the parameters we needed for Naive Bayes – the various probabilities – can be extracted from the matrix X .

For example, suppose we have a collection of images represented as black/white pixels in a grid that belong to one of two classes. For example, we might have 28×28 bitmaps of handwritten zeros and ones that are labelled, and we wish to construct a classifier that can decide whether a new 28×28 bitmap is a zero or one. An example of such a bitmap is given in fig. 1. We can view each 28×28 bitmap as a vector of length 784 with 0/1 entries and apply the same approach outlined above.

Figure 1: Handwritten 0

1.7 Other models: the binomial and gaussian models.

We have discussed a version of Naive Bayes based on the Bernoulli model, in which we imagine applying a set of independent yes/no tests to some data to determine its most likely class. Concretely, in our sentiment analysis problem, we looked for the presence or absence of certain words, but paid no attention to whether a word occurred more than once.

The binomial model is an alternative approach to the Bernoulli model and takes a different point of view on the text data. It is sometimes called the “bag of words” model. Suppose I have a vocabulary of words w , and two types of documents \pm . For each word we have probabilities $P_+(w)$ and $P_-(w)$ that measure the chance that a particular word in each class is the given word. These probabilities can be derived in a naive sense by looking at the frequency with which they occur in documents of the two classes. In this statistical model a document in class $+$ is constructed by successively choosing words from the vocabulary according to the probabilities $P_+(w)$.

Given a document to classify, one looks at the frequencies of the vocabulary words and computes the likelihood of that distribution in each of the two classes,

and chooses the more likely class.

This approach is better suited to longer documents, and it requires working with large vocabularies, but it does take account of how often the vocabulary words appear in the document.

The Gaussian model takes a different approach and is useful for classifying numerical data. Given a set of labelled training data, one assumes that each feature comes from a normal distribution, with the mean and variance depending on the associated class. One uses the training data to estimate these means and variances. Then, given a piece of data to classify, one computes the likelihood of the data arising from the two different classes, and chooses the more likely one.

What unites all of these methods under the heading of Naive Bayes is that the parameters are estimated simply from empirical data – that’s the naive part – and Bayes theorem is used to compute the likelihood of membership in each of the two classes.
